1. Introduction

The compression is an important area of research in image processing and has been widely studied in the last decades. Compression algorithms can restitute the exact information (Lossless methods) or introduce a little distortion (lossy methods). The Lossless image compression is designed to reduce or remove the image’s redundancy. They have weak compression ratio but benefit from an exact reconstruction of the image. The purpose of lossy image compression is to minimize the number of bits needed to represent an image without introducing an important degradation. Natural images have an important redundancy among the space-image pixels. A linear transformation is applied to minimize redundancy in the images since it can decorrelate pixel values in the transform domain. The international standard for still image compression, called Joint Photographic Experts Group or JPEG standard [1]-[2], uses the Discrete Cosine Transform (DCT) [3]-[4]. The JPEG2000 [5] uses The Discrete Wavelet Transforms (DWT). The quantization assigns to each transform coefficient a number of bits according to its position. This step is not conservative and attempts to reduce the number of samples. Finally, an entropy encoder codes these samples [6]-[8]. The main objective of the image compression is to achieve the lowest bit rate without loss of the visual information. It implies a distinction between the visible and invisible information contained in an image. This distinction is done by the exploitation of a human visual model, incorporated within the compressive process, precisely at the quantization stage. The key element of such a model is the Contrast Sensitivity Function (CSF). This Function describes the human visual sensitivity to different spatial frequencies by varying their contrast. Its curve shows essentially that the
sensitivity of the visual system is reduced for structures of high spatial frequencies. The exploitation of the CSF at the quantization phase permits to select the truncation of the information contained in the image. In other words, the truncation affects intensively the spatial high frequency information and assures the visually important spatial frequency preservation. Therefore this method permits to improve the visual quality of the compression significantly.

2- The HVS characteristics and image compression

2.1- Presentation
The human visual system (HVS) reached during the evolution an important level of complexity. It is capable to execute several tasks that can’t be achieved by the present technology. Nevertheless, it has some limitations concerning the visual perception. These minor imperfections don't make uncomfortable the vision. However these limitations can be exploited in image compression. One of the most important limitations of the HVS system concerns the sensitivity reduced for the spatial high frequency structures. This phenomenon is shown by the contrast sensitivity function (CSF).

2.2 The contrast sensitivity function
The function of sensitivity to the contrasts, commonly called Contrast Sensitivity Function (CSF), describes the capacity of the human visual system to detect differences of luminance. The researchers studied the variation of the contrast sensitivity according to the different spatial frequencies. They are represented by a stimulus with a periodic structure formed of alternate strips. The gotten curve constitutes the function of contrast sensitivity (CSF) of the examined person considering the conditions of the experimentation: shape of the stimulus, distance of vision, angle of vision, binocular or monocular vision etc.
Studies have been led to find some analytic formulas close to the experimental results. Among the most known, we mention the formula of Mannos and Sakrison [9]. It is one of the first solutions and it is used in many studies.

\[
CSF(f) = 2.6 \left( 0.0192 + 0.114f \right) e^{-\left(0.114f\right)^2}
\]  

(1)

Other formulas have been proposed [10-11]. The most recent is the one of Ngan [12].

### 2.3 Quantization and contrast sensitivity function

The compression by Discrete Wavelet Transforms (DWT) is accomplished with a quantization and an entropy encoder. Typically, one uses a constant quantifier implemented by a division of the wavelet coefficients by a constant factor Q. The result is approximated to the nearest integer [13]. The factor Q can be different for different intervals of frequency. It is then appropriate to speak of a quantization matrix to make reference to a set of factors. It corresponds to a particular matrix related to a level of decomposition. The matrix that illustrates the increasing quantization is given by the Fig. 2. The integer q is the quantum chosen to determine the step of the quantization. The idea of this method consists to reduce the precision of the coefficients of the DWT while moving away of the

region of low frequencies (coefficients of the approximation). Indeed, it is not necessary to maintain an important precision on the coefficients of high frequencies because these values are less relevant than the ones of low frequencies.

4q+1 & 5q+1 & & \\
6q+1 & 7q+1 & & \\
\end{array}
\]

**Figure 2: The matrix of quantization**

Our aim is to define the terms of a new matrix of quantization by taking into account the HVS characteristics and particularly the Contrast Sensitivity Function. These terms have to increase while moving to the region of high frequencies.

3. **CSF based Quantization**

To exploit the CSF in the process of the wavelet transform based quantization, we use the invariable unique weight. In other words, only one factor is affected for every wavelet subband. This factor remains constant during the whole phase of quantization. The set of these quantization factors is called CSF Quantifier. Fig. 3 illustrates the incorporation of the CSF Quantifier in the compression process.
IDWT is The inverse of DWT. The advantages of this method reside in the simplicity of the determination of the quantization factors and the reduction of the computational time. The quantization factors are inversely proportional to the sensitivity average of the HVS on the frequency band related to each subband of the wavelet transform. Indeed, every subband of the wavelet transform occupies an interval on the spatial frequencies. Therefore, we compute the average of the CSF on every interval of the spatial frequency and we define the CSF quantifier factors as the inverses of these averages. Then they are normalized so that the smallest of these factors is equal to 1 (Fig. 4). On given one interval, more the CSF is raised, more its spatial frequencies are relevant and more the coefficient of quantization is low. For a wavelet decomposition of level 5, this method gives 6 CSF weights. Let us define $w_{csf}(\lambda)$ as the CSF weight related to the level $\lambda$ of the wavelet decomposition. Fig. 5 shows the new matrix of quantization where the details coefficients of level $\lambda \in \{1,2,3,4,5\}$ are pondered by the coefficients $w_{csf}(\lambda)$, and the approximation coefficients are pondered by the factor $w_{csf}(6)$.

**Figure 3: The incorporation of the CSF Quantifier**
To optimize our method, we introduce two parameters in the CSF quantifier. The first is noted $m$. It multiplies the coefficients of the CSF quantifier to adjust the compression ratios. The second is a parameter that raises the coefficients of the CSF quantifier to a power noted $p$. The main interest of this factor is to increase the truncation of the coefficients corresponding to the high spatial frequencies. Indeed, the sensitivity of the SVH system is reduced for these frequencies. On the other hand, our method preserves the perceptible information. In fact, the coefficients of the CSF quantifier related to spatial frequencies of this perceptible information have a value very close to 1. Therefore, an elevation to the power of $p$ nearly preserves the totality of the information after the phase of quantization. Let us define $\Omega_{\text{csf}}(\lambda)$ as the CSF weight $w_{\text{csf}}(\lambda)$ optimized by the parameters $m$ and $p$. They are given by:

$$\Omega_{\text{csf}}(\lambda) = m \cdot (w_{\text{csf}}(\lambda))^p$$  \hspace{1cm} (2)
4. Image quality assessment

To evaluate our method, we use the Peak Signal to Noise Ratio (PSNR), which is defined as:

\[
PSNR = 10 \log_{10} \left( \frac{(255)^2}{MSE} \right)
\]  

(3)

where \(MSE\) is the Mean Square Error:

\[
MSE = \frac{1}{MN} \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} |x(m,n) - \hat{x}(m,n)|^2
\]  

(4)

where \(M\) and \(N\) are the number of lines and columns of the image, \(x(m,n)\) and \(\hat{x}(m,n)\) are the pixels of the original and the processed image. However, the PSNR do not correlate well with subjective quality evaluation. In fact, the HVS is sensitive to the noise on the uniform zones. Its perception on the textured zones is more difficult. To take into account this characteristic of the HVS, we use the weighted PSNR (wPSNR) that use the local variance of the image to ponder the error:

\[
wPSNR = 10 \log_{10} \left( \frac{(255)^2}{wMSE} \right)
\]  

(5)

where

\[
wMSE = \frac{1}{MN} \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} \frac{x(m,n) - \hat{x}(m,n)}{1 + \text{var} (m,n)}
\]  

(6)
5. Results
We applied our method to four images: two medical images, Lena and Bird. The size of these images is of 256×256. We used the 5/3 wavelet of Le Gall. We compare the HVS quantifier and a conventional quantization by using the matrix shown in Fig. 2. Table 1 shows that the HVS quantifier performs better results than the conventional quantization. This is reasonable since the HVS quantifier allocates less bits to the wavelets coefficients related to the frequencies bands which are weakly perceptible. Subjective testing performed on the Forearm image and Lena image (Fig. 6) shows that the reconstructed images by using the perceptual method have a better quality. We notice that the reconstructed images by using the conventional method are blurred. Perceptual method preserves the edges better on the reconstructed images.

6. Conclusion
A perceptual image coding method by using the wavelet transform was proposed in this paper. This method takes into account the characteristics of the Human Visual System (HVS) by incorporating the Contrast Sensitivity Function (CSF) in the quantization step. This function describes the capacity of the human visual system to detect differences of luminance according to the different spatial frequencies. To evaluate our method, we use the weighted Peak Signal to Noise Ratio (wPSNR) that uses the local variance of the image to ponder the error. The objectives results showed that the perceptual method outperforms the conventional method. The subjective testing showed that the perceptual method has a better quality.
